(Dated: October 7, 2015)

We study experimentally and computationally the dynamic flow of granular material during impacts, where intruders strike a collection of disks from above. In the regime where granular force dynamics are much more rapid than the intruder motion, we find that the particle flow near the intruder is proportional to the instantaneous intruder speed; it is essentially constant when normalized by that speed. The granular flow is nearly divergence-free and remains in balance with the intruder despite the latter’s rapid deceleration, which may explain similarities between impacts and steady drag experiments. Simulations indicate that this observation is insensitive to grain properties, including friction, although friction has a substantial effect on the intruder dynamics (e.g., the final penetration depth). The separation of time scales between grain and intruder dynamics explains the insensitivity to grain properties. Our results suggest that other time-dependent granular flows may have similar dependence on the rate of external driving, if a comparable separation of time scales applies.

What is the nature of force transmission and particle flow during intrusion into granular material? This question is fundamental to a general understanding of dense granular flow, and a complete description would be useful in many natural and industrial phenomena. There are two common variations of this problem: an intruder that is dragged through a granular medium at a fixed speed, and impact, where an intruder strikes the surface of a granular bed and is decelerated. In the case of constant velocity, the force exerted by the grains on the intruder is rate-independent and velocity-squared drag forces studied previously. When \( v_0 \ll v_f \), the fast force transmission speeds mean that the material responds quickly to the advancing intruder, and the quasi-random collisions with force-chain-like structures \( v_f \) yield a velocity-squared drag force with a drag coefficient that is nearly constant over the intruder trajectory \( v_f \). However, the grain-scale force picture and the subsequent intruder dynamics change drastically when the intruder speed becomes similar to granular force transmission speeds \( v_f \).

To complement previous work on force dynamics, we present experimental and computational results on the flow of a 2D granular material around circular intruders that are normally incident on a free granular bed from above at speeds \( v_0 \leq 6 \text{ m/s} \). The experiments are carried out using the protocol described in \( v_f \). These studies showed that the deceleration is dominated by large fluctuations in space and time in the form of quasi-random collisions with networks of particles. On longer time scales, these fluctuating forces average to the rate-independent and velocity-squared drag forces studied previously. When \( v_0 \ll v_f \), the fast force transmission speeds mean that the material responds quickly to the advancing intruder, and the quasi-random collisions with force-chain-like structures \( v_f \) yield a velocity-squared drag force with a drag coefficient that is nearly constant over the intruder trajectory \( v_f \). However, the grain-scale force picture and the subsequent intruder dynamics change drastically when the intruder speed becomes similar to granular force transmission speeds \( v_f \).

To explicitly explore how these fast force dynamics relate to the intruder motion, we have previously studied granular impact experimentally using high-speed imaging of intruder impacts into beds of photoelastic disks \( v_f \). These studies showed that the deceleration is dominated by large fluctuations in space and time in the form of quasi-random collisions with networks of particles. On longer time scales, these fluctuating forces average to the rate-independent and velocity-squared drag forces studied previously. When \( v_0 \ll v_f \), the fast force transmission speeds mean that the material responds quickly to the advancing intruder, and the quasi-random collisions with force-chain-like structures \( v_f \) yield a velocity-squared drag force with a drag coefficient that is nearly constant over the intruder trajectory \( v_f \). However, the grain-scale force picture and the subsequent intruder dynamics change drastically when the intruder speed becomes similar to granular force transmission speeds \( v_f \).
FIG. 1. (color online.) (a) PIV flow field for a circular intruder with radius $R = 6.35$ cm at a particular frame. (b) Vertical and horizontal components of the spatially smoothed PIV flow field from experiment, normalized by the instantaneous intruder velocity ($v = 3.05$ m/s). The left panel shows the normalized vertical velocity, $u_z/v$, with downward as positive, and the right panel shows the horizontal velocity, $u_x/v$, with rightward as positive. The white color in the intruder in the left panel denotes its downward motion. The red box encloses the region used to obtain the steady-state velocity field, which will move along with the intruder. (c) The instantaneous flow fields, $u_x/v$ and $u_z/v$, at a particular time from simulations with Hertzian, frictional interactions between grains.

nature of this process. By dynamic equilibrium, we mean that as the intruder moves through the granular material, the flow field near the intruder scales linearly with the instantaneous intruder speed, even as the intruder decelerates rapidly. Since $v_0 \ll v_f$, the force dynamics are much faster than intruder motion, and forces propagate and relax fast enough that the motion of grains near the intruder is essentially incompressible and always scales linearly with the intruder’s speed.

The techniques for the accompanying simulations are described in detail in SM, and here we provide just an overview. The particle and the intruder are modeled as inelastic, frictional disks, and only circular intruders are considered. The container walls are modeled by a layer of stationary strongly inelastic particles. The number of particles and their size distribution are matched to the experiments, as are the material parameters (friction and restitution coefficient, Young modulus, Poisson ratio). The simulations implement a standard Cundall-Strack model to describe frictional interactions, although some simulations are carried out without friction. The simulations with a linear force model are carried out as described in [17]; in particular, the force constant needed to compute the normal force between the particles is based on the requirement that the binary contact times agree with the nonlinear force law found experimentally (see [18]). The nonlinear simulations use a Hertzian interaction potential, with the force constant computed by fitting the experimental data obtained by statically compressing granular particles (see [16]).

Experimentally, the flow fields are calculated using particle image velocimetry (PIV) [19], which analyzes successive pairs of frames from high-speed movies to estimate the local flow field. This returns estimates of the local displacement on a grid, as shown in Fig. 1. Results from PIV (for experiments) or actual particle positions and velocities (for simulations) can then be coarse-grained, as shown in Fig. 1(b) and (c), to give a continuum flow field $\mathbf{u}(x,t)$, where $x$ represents spatial coordinates in the lab frame. The vertical component, $u_z(x,t)$ (with downward being positive $z$), and the horizontal component, $u_x(x,t)$ (with rightward being positive $x$) components of the flow field at are shown in Fig. 1(b) for experiments. The grid size used for the PIV algorithm is approximately the same size as a single particle, so the particle-scale fluctuations in the velocity fields still persist. To compare simulation results to PIV, we use a coarse-grained momentum field normalized by a typical mass density, as shown in Fig. 1(c) (see SM for details).

In both experiments and simulations, we find that

$$u(x,t) = v(t) \left[ A(x - x_0) + A'(x - x_0, t) \right], \quad (1)$$

where $v(t)$ is the intruder speed (with motion assumed to be strictly downward), $x_0(t)$ is the intruder position in the lab frame, $A$ is the scaled steady-state velocity field, and $A'$ captures the instantaneous fluctuations in the velocity field. $A$ is shown in Fig. 2(a) for experiments and in SM for simulations. $A$ for simulations appears identical to Fig. 2(a), and we quantitatively show that they agree in our analysis below. In each experimental trajectory, we calculate $A$ by averaging over approximately 300 pairs of frames, sampled at $2333$ Hz, using flow-field data inside the red rectangular region marked in Fig. 1(b) at each frame where this rectangular region is entirely in the field of view. $A$ appears very similar to the instantaneous
experiment (see SM). The magnitude \( A' \) at one instant is shown in Fig. 2(b), with \( A' \) determined at each time from the difference between the instantaneous coarse-grained flow field and the average flow field, \( A' = u/v(t) - A \). An experimental measurement of \( A' \) at one instant is shown in Fig. 2(b), which is typical for all times in both simulation and experiment (see SM).

Using numerical derivatives, we find that \( A \) is divergence free within noise, and thus the flow of grains near the intruder is essentially incompressible (see SM). The magnitude \( |A'| \) is always small, Figure 2(c), with \( |A'| < 0.2 \) (where a value of 1 would correspond to a local velocity fluctuation of the same size as the intruder speed); it is largest near the leading edge of the intruder and falls off rapidly with increasing distance from the intruder. \( A' \) is statistically stationary in time and decoupled from the intruder dynamics. We also find that \( A' \) is spatially well correlated to gradients in \( A \) [23, 24]; see SM for details. Physically, \( A' \) represents non-affine particle rearrangements as particles are forced to move past each other, as opposed to a systematic evolution related to the intruder motion.

To fit \( A \) to a functional form, it is decomposed into radial and angular components

\[
A(x) = \hat{r}[\cos \theta - A_r(r)] + \hat{\theta}[A_\theta(r) - \sin \theta].
\]

Here, \( r = \hat{r} \theta + \hat{\theta} \), where \( r = 0 \) corresponds to the center of the intruder, \( \theta \) is measured from the (downward) \( z \)-axis. Shifting by \( \mathbf{z} = \cos \theta \hat{r} - \sin \theta \hat{\theta} \) corresponds to a transfer from the lab frame to the intruder frame. \( A_r \) and \( A_\theta \) are defined as

\[
A_r(r) = a_r(r) \cos[b_r(r) \theta]
\]

\[
A_\theta(r) = a_\theta(r) \sin[b_\theta(r) \theta].
\]

Seguin et al. [4, 5] used a similar form to describe quasistatic granular flow around downward-moving circular obstacles, but with \( b_r = b_\theta = 1 \), since, in their quasistatic case, the flow was symmetric ahead of and behind the intruder. Here, we consider fits only to the half-space in front of the intruder. Sample fits at particular values of \( r \) are shown in Fig. 3. Far away, all four fit parameters should approach 1, corresponding to no grain motion.

Figure 3 shows \( a_r(r) \), \( b_r(r) \), \( a_\theta(r) \), and \( b_\theta(r) \) for different circular-nosed intruders with radii \( R = 3.18, 4.65, 6.35, \) and 10.15 cm. The intruder with \( R = 4.65 \) cm is an ogive, with a circular nose and rectangular tail; however, the particles are never in contact with the tail, so that its presence is irrelevant, aside from increasing the area of the intruder and therefore its effective mass. The fit parameters for each intruder appear similar when rescaled by \( R \), with secondary dependencies on the ratio \( \rho_{nt}/\rho_g \) of intruder to grain mass density and on the ratio \( d/R \) of grain size to intruder radius, where \( d \approx 5 \text{ mm} \). \( a_r \) and \( b_r \) decay roughly exponentially to their far-field values as \( a_r \propto \exp(-R/\xi_n) \) and \( b_r \propto \exp(-r/\xi_n) \), with \( 0.25R < \xi_n < 0.7R \) and \( \xi_n \approx 1.85R \). This localization and exponential spatial decay is also common in dense granular flows that are driven by a boundary (e.g., Refs. [4, 5, 24], and many others).

To test sensitivity to the grain-grain force law, we perform simulations with frictional Hertzian, frictional linear, and frictionless linear force interactions between the particles. Figure 4 shows a comparison between the fit of experimental and computational data to Eqs. (2) - (4) for a single size intruder; this is typical for all sizes, as we show in SM. We find surprisingly good agreement for all considered force models. Such a good agreement
shows that in the present regime, the details of the force model are not crucial for the response of granular material to impact. However, we note that frictional forces still play an important role in determining dynamics of the intruder; in particular, without friction, the final penetration depth is almost 50% larger than when friction is present (see SM). The functional form of the normal forces between the particles (linear versus non-linear) however does not appear to be important. We attribute this finding to the fact that we consider the regime such that \( v_0 \ll v_f \); the functional form of the force model becomes important when this condition is not satisfied [10, 23].

These results provide several important physical insights. First, while the force response here, where grain forces are imbalanced and the force response scales quadratically with driving rate, clearly distinguishes impact from quasi-static processes, where grain forces are nearly balanced and rate-independent, we find that particle motion scales linearly with driving speed, as in quasi-static systems. This is made possible in both cases by the large difference between the force transmission speed \( v_f \) and driving speed \( v_0 \), as is common in impact flows. Conversely, it is possible that models such as granular impact [30], where the flow is transient, provides \( v_0 \ll v_f \). We note that the response of the granular material to impact when the condition \( v_0 \ll v_f \) is not satisfied is significantly different [10].
