Brain natriuretic peptide (BNP) levels are lower in obese patients with left ventricular failure than in their comparably ill, leaner counterparts. The effect of obesity on BNP in patients with pulmonary arterial hypertension (PAH) is unknown. We reviewed our prospective PAH registry data collected from November 2001 to December 2007 for patients undergoing right heart catheterization who met the criteria for PAH and had the BNP level and body mass index determined at baseline. The median BNP level for the lean, overweight, and obese patients was 285 pg/ml (interquartile range 131 to 548), 315 pg/ml (interquartile range 88 to 531), and 117 pg/ml (interquartile range 58 to 270), respectively (p = 0.029). A greater body mass index was associated with a lower BNP level, adjusted for age, gender, New York Heart Association functional class, hypertension, coronary artery disease, and mean right atrial and pulmonary arterial pressures (p < 0.001). No statistically significant differences were found among the groups in age, race, medical co-morbidities, underlying etiology of PAH, use of vasoactive medications, New York Heart Association functional class, echocardiographic parameters, or pulmonary function. Obese patients had greater right atrial and pulmonary artery pressures. Increased BNP was associated with worse survival in the lean and overweight patients only. In conclusion, the BNP levels are attenuated in obese patients with PAH despite similar or worse hemodynamics or functional class compared to lean or overweight patients and should therefore be interpreted with caution. © 2012 Elsevier Inc. Methods

We reviewed a large, single-center, prospectively collected database of consecutive patients undergoing right-sided heart catheterization for evaluation of PAH from November 2001 to December 2007. Patients <18 years old, those with a diagnosis of heart failure, and those requiring dialysis were excluded. Of the 530 patients undergoing right-sided heart catheterization, 380 did not have PAH, 42 patients did not have the baseline BNP measured, and 4 did not have the baseline BMI determined and were excluded, leaving a study population of 104 patients with World Health Organization category I PAH. Heart failure and PAH were defined according to the established guidelines.11,12

We reviewed our institutional review board-approved registry for demographics, medical history, PAH classification,12 pulmonary vasodilator medication use, New York Heart Association (NYHA) functional class, 6-minute walk distance, serum BNP (using the Biosite assay), blood urea nitrogen, serum creatinine, pulmonary function test data, transthoracic echocardiographic data, hemodynamic data, and Social Security Death Index data. Coronary artery disease, hyperlipidemia, and hypertension were defined according to established guidelines.13 The included data were within 2 months of the diagnostic right-sided heart catheterization. Data were missing for the following variables: echocardiography (2% missing), creatinine (0.9% missing), NYHA functional class (0.9% missing), 6-minute walk test (16% missing). All patients had the hemodynamic data...
measured; however, 14% had ≥1 variable obtained using right-sided heart catheterization missing.

Patients were grouped according to their BMI as lean (<25.0 kg/m²), overweight (25.0 to 29.9 kg/m²), or obese (≥30.0 kg/m²). The quantitative variables are summarized within the BMI group as the mean ± SD, except for the BNP levels, for which the median and interquartile range are reported. The quantitative variables were compared using the Kruskal-Wallis test and the categorical variables using chi-square tests. Within the BMI groups, comparisons with respect to dichotomized patient characteristics were performed with Wilcoxon rank sum tests. Multivariate linear regression analysis of continuous log-transformed BNP versus obesity and covariates reflective of disease severity was performed. Cox regression analysis using backward stepwise elimination of variables with Wald p > 0.10 as a removal criterion was used to determine the relation of BNP in its log-transformed form to survival. Receiver operating characteristic curves were used to assess the associations between BNP and 2-year survival, with the optimal BNP cutoff values estimated within each BMI group. These cutoffs were then applied to an analysis of overall survival using Kaplan-Meier curves and log–rank tests for comparison. A Cox regression model of survival with respect to log₂BNP, BMI, and their interaction was used to evaluate the strength of the relation between BNP and survival for the different BMI values.

Survival was estimated from the date of right heart catheterization until cardiopulmonary death or until September 2009 using the patient medical records, pulmonary hypertension database, and the Social Security Death Index. None of the 104 patients included in the present study received a lung or a heart-lung transplant during the study period.

**Results**

The mean age of the study population at the baseline diagnostic right heart catheterization was 51 ± 3 years; 85% were women, 85% were European American, and 14% were African American. The etiology of PAH was idiopathic in 48%, connective tissue disease in 27%, portal hypertension in 13%, congenital heart disease in 10%, human immunodeficiency virus related in 1, and drug related in 1. The medications used included prostanooids (50%), endothelin receptor blockers (23%), phosphodiesterase V inhibitors (20%), 11% were not taking pulmonary vasoactive medications, and 5% were receiving combination therapy. The patient characteristics according to the BMI groups are listed in Table 1. No statistically significant differences were found between groups in terms of age, race, medical co-morbidities,
underlying PAH etiology, use of vasoactive medications, NYHA functional class, echocardiographic parameters studied, or pulmonary function. Obese patients had greater right atrial and mean pulmonary artery pressures.

The plasma BNP was significantly lower in obese patients with PAH compared to that in the overweight or lean patients. The median value for lean, overweight, and obese patients was 285 pg/ml (interquartile range 131 to 548), 315 pg/ml (interquartile range 88 to 531), 117 pg/ml (interquartile range 58 to 270), respectively ($p = 0.029$). This was true despite a 6-minute walk distance that was not significantly different among the BMI categories ($p = 0.40$; Figure 1). The degree of BNP attenuation among obese subjects was more pronounced in patients aged ≥55 years ($p < 0.001$) and in women ($p = 0.015$; Figure 2).

Univariate analysis of log-transformed BNP versus BMI was performed and demonstrated that a greater BMI was associated with a lower BNP ($p = 0.011$). This association was maintained with covariate adjustment for age, gender, NYHA class, hypertension, coronary artery disease, and mean right atrial and pulmonary arterial pressures ($p < 0.001$).

The patients were followed up for a mean of 3.0 ± 0.2 years. During follow-up, 49 patients died: 25 by 1 year and 32 by 2 years. The mean survival rate was not significantly different statistically among the BMI groups (log-rank $p = 0.10$), with a 2-year survival rate of 77% for lean patients, 66% for overweight patients, and 68% for obese patients. In the study population, BNP was significantly associated with survival, independent of age, BMI, creatinine, and presence of a pericardial effusion on transthoracic echocardiography ($p = 0.01$). Receiver operating characteristic analysis was performed in each BMI group and revealed an optimal cutoff of 361 pg/ml for lean patients, 406 pg/ml for overweight patients, and 50 pg/ml for obese patients (Figure 3). However, in obese patients, the area under the curve was only 0.55, suggesting that the BNP level might not be a useful prognostic indicator in obese patients with PAH.

These values were then used to construct the Kaplan-Meier curves (Figure 4). The strength of the association of BNP and survival gradually weakened as the BMI increased, and, in patients with a BMI of ≥35 kg/m², this relation was lost (Figure 5).

**Discussion**

An increased serum BNP level is thought to reflect poorer functional capacity, greater hemodynamic impairment and reduced survival in subjects with PAH. In our study, obese patients with PAH had greater pulmonary artery and mean right atrial pressures and similar functional status (NYHA class and 6-minute walk distance) compared to their leaner counterparts but had lower serum BNP levels. Although greater BNP levels have been shown to predict reduced survival in patients with PAH, we found that BNP was not a good predictor of survival in obese patients with PAH.

Serum BNP levels have been shown to be significantly lower in obese patients in the absence or presence of heart failure. In patients with left-sided heart fail-
lower circulating levels of BNP have been reported in obese subjects, despite similar heart failure severity, compared to leaner subjects. Furthermore, the BNP levels have been shown to predict mortality in patients with heart failure in all BMI categories, although lower cutoffs have been suggested for patients with an elevated BMI. In our study, we found a similar relation of decreasing BNP levels with obesity in patients with PAH that remained statistically significant on multivariate analysis. Our results have confirmed previous reports of the prognostic significance of BNP in patients with PAH. However, our study also showed that BNP does not appear to be a robust prognostic marker in those with PAH with a high BMI and that the relation between BNP and survival is statistically significant only in patients with a BMI <35 kg/m².

The cause of BNP attenuation in obese subjects is uncertain. Increased clearance could certainly play a role because removal of the BNP molecule is facilitated by the natriuretic peptide C receptor found in abundance on adipose cells. Alternatively, it is possible that decreased BNP production might be reduced in the setting of obesity. This was suggested by the observation that the levels of N-terminal pro-BNP also tend to be lower in obese subjects. N-terminal pro-BNP is not cleared by the natriuretic peptide C receptor and serum levels of this pro-molecule correlate with the lean body mass rather than the BMI. Both BNP
and N-terminal pro-BNP have been shown to increase with significant weight loss after bariatric surgery. 

Our study had limitations. The BMI was generally determined at right-sided heart catheterization and the BNP, functional status, and echocardiographic data were obtained within 2 months of heart catheterization. Our sample sizes within each BMI group were small; thus, BNP associations with NYHA functional class and hemodynamics could not be reliably performed because of the lack of statistical power. An increased BMI can result
not only from increased adipose tissue, but could also indicate fluid retention from ascites, peripheral edema, and progressive right-sided heart failure. Consequently, the measures of fat mass or percentage of body fat would have been more desirable and should certainly be a component of any future prospective study. Fluid retention could have contributed to the BNP levels not being significantly different between the lean and overweight groups and the trend toward being greater in the overweight group. Nevertheless, obese patients in the present study had the lowest BNP levels despite similar or more severe disease compared to the lean or overweight patients. Finally, some variables in our database had missing data, although it was prospectively constructed.
